## ABSTRACT

In many situations, interdependency between motion estimation and other estimation tasks is observable. This is for instance true in the area of Super-Resolution (SR) [1]. In order to successfully reconstruct a SR image, accurate motion vector fields are needed. On the other hand, one can only get accurate (subpixel) motion vectors, if there exist highly accurate higher-resolution reference images. Neglecting this interdependency may lead to poor estimation results - for motion estimation as well as for the SR image. To address this problem, a new motion estimation scheme is presented that jointly optimises the motion vector field and a SR reference image. For this purpose and in order to attenuate aliasing and noise, which deteriorate the motion estimation, an observation model for the image acquisition process is applied and a Maximum A Posteriori (MAP) optimisation is performed, using Markov Random Field image models for regularisation. Results show that the new motion estimator provides more accurate motion vector fields than classical block motion estimation techniques. The joint optimisation scheme yields an estimate of the motion vector field as well as a SR image.

## 1. INTRODUCTION

Motion estimation is an important research topic in image and video processing as well as in computer vision. Understanding how objects move is a field of high practical interest, covering a broad range of applications in many engineering fields such as video object tracking [2], Super-Resolution image reconstruction [1], video compression [3] and medical engineering [4] to name a few. An accurate estimate of the motion vector field is the first and crucial step for successful results in the aforementioned applications.

One popular approach to motion vector field estimation is blockmatching [3]. In blockmatching, images of interest are divided into blocks. Matching blocks (i.e. those that represent the same physical feature) are searched for in a reference image. The spatial displacement between two matching blocks

is said to correspond to the motion of the physical region they represent, i.e. the motion vector. Assuming a short time distance between two images of a video sequence, a translational motion model for small image blocks is sufficient to describe the spatial displacement.

Let  $b_{1,k}$  be a vectorised image block taken from a grayscale image of interest. Its elements are in lexicographic notation. Further, let  $b_{0,l}$  be a vectorised image block in a reference image. The aim of block matching is to find the block  $b_{0,\bar{l}}$  that corresponds to the same physical region as  $b_{1,k}$ . Making the assumption of intensity conservation, i.e. pixel intensities are assumed to be constant within a tracking period, motivates the use of the Sum of Absolute Differences (SAD) as a measure of similarity between a block  $b_{1,k}$  and a reference block  $b_{0,l}$ . Besides the SAD there are a number of other distance measures such as the SSD (Sum of Squared Differences), SATD (Sum of Absolute Transform Differences) and SSTD (Sum of Squared Transform Differences). We restrict ourselves to the SAD as we found the remaining measures having comparable performance. The SAD block matcher with full search works as follows:  $b_{1,k}$  is compared to all possible (overlapping) blocks  $b_{0,l}$  in a search area of the reference image. The matching block  $b_{0,\bar{l}}$  is then calculated as the one which leads to the lowest SAD. For high-precision motion estimation fractional pixel accuracy is needed.

In order to increase the motion resolution to  $\frac{1}{p}$  pixels, it is common to increase the image size by a factor of  $p$  by using an interpolation scheme and to perform the block matching on the interpolated images. The quality of motion estimates with subpel resolution is highly dependent on the accuracy of the interpolated, higher-resolution reference image. If an input image is a downsampled, aliased and noisy observation of an unknown image of higher resolution a simple interpolation scheme results in an unsatisfactory approximation.

In general, the principle of intensity conservation is well motivated, however it may be violated due to aliasing effects and noise which occur at the image acquisition step. Especially when small block sizes are used, motion estimation based on the assumption of block similarity will consequently fail when aliasing and noise are present. Furthermore, classical blockmatching schemes neglect interdependency between the

motion estimation itself and other estimation tasks. This may also lead to poor performance. In this paper we explicitly deal with this interdependency with a joint motion and Super-Resolution estimation scheme.

The rest of the paper is organised as follows: Section 2 presents the the data model for the image acquisition process which is used throughout this paper. Section 3 gives a short review of the stochastic regularisation approach for SR image reconstruction. In section 4 the new motion estimation scheme based on SR is presented, simulation results are shown in section 5. Finally, section 6 provides conclusions.

## 2. DATA MODEL

The following data model will be used throughout this paper:

$$y_i = DB_i M_i x + \eta_i, \quad i = 0, \dots, L-1 \quad (1)$$

with  $y_i$  being the vectorised  $i$ th input block,  $D$  being the downsampling matrix,  $B_i$  being the blurring matrix for the  $i$ th input block,  $M_i$  being the motion matrix describing the spatial displacement of the input images,  $x$  being the true underlying High Resolution (HR) block which is assumed to be sampled from a continuous scene at or above the Nyquist rate and  $\eta_i$  being the  $i$ th noise vector.

Equation (1) states that the observation signals  $y_i$  are low dimension projections from a common underlying (and unknown) signal  $x$  of high dimension. The projection is described in terms of the matrix  $DB_i M_i$ . Furthermore, noise is added to the observations.

## 3. STOCHASTIC REGULARISATION

Here we will assume the blurring to be time invariant, i.e.  $B_i = B \forall i$ , and be described by a space invariant averaging point spread function. As  $D$  is fixed and determined by the downscaling ratio, the only unknowns are  $M_i$ ,  $x$  and  $\eta_i$ , i.e. the information how the two blocks are aligned, the true underlying block of higher resolution and the noise. Let us for the time being assume  $M_i$  to be fixed (e.g. one possible motion which we wish to test). Then the problem narrows down to a SR problem, estimating the common High Resolution (HR) image from a set of displaced Low Resolution (LR) images. Making the assumption of  $\eta_i$  to be i.i.d. zero mean Gaussian distributed and making use of a Markov Random Field (MRF) [5] describing the relationship between neighbouring pixels, a maximum *a posteriori* approach maximising  $P(x|y_0, \dots, y_{L-1})$  can be made, resulting in a least squares solution with a regularisation term [1]:

$$\hat{x} = \arg \min_x \left\{ \sum_{i=0}^{L-1} (y_i - DBM_i x)^T (y_i - DBM_i x) + c \sum_{s \in S} \phi_s(x - Nx) \right\} \quad (2)$$

with  $c$  being the regularisation parameter,  $\phi_s(x - Nx)$  being a penalty function depending on the pixel values within a local group of pixels  $s$  and  $S$  denoting the set of local groups.  $N$  is a neighbourhood matrix replacing each sample with the mean value of its 4-neighbourhood. Thus  $x - Nx$  is a simple activity measure which has a high absolute value if discontinuities in the image are present and a small absolute value if the values of neighbouring samples are close.

Taking the derivative of the argument in Equation (2) with respect to  $x$  and setting it to zero leads to:

$$\sum_{i=0}^{L-1} (DBM_i)^T (y_i - DBM_i x) = \frac{c}{2} \sum_{s \in S} \frac{\partial \phi_s(x - Nx)}{\partial x} \quad (3)$$

which can be solved by, for example, the Conjugate Gradient (CG) algorithm [6]. We will treat three MRF image models, namely the Gaussian, Huber and Double-Exponential MRF, resulting in different penalty functions for regularisation: Gaussian Markov Random Field (GMRF):

$$\phi_{s,G}(x) = x^2 \quad (4)$$

Huber Markov Random Field (HMRF):

$$\phi_{s,H,\alpha}(x) = \begin{cases} x^2 & \text{for } |x| \leq \alpha \\ 2\alpha|x| - \alpha^2 & \text{for } |x| > \alpha \end{cases} \quad (5)$$

Double-Exponential Markov Random Field (DEMRF):

$$\phi_{s,D}(x) = |x| \quad (6)$$

Note that when using the HMRF or DEMRF image model Equation (3) turns into a nonlinear equation system which requires a far more complex nonlinear optimisation.

## 4. THE MOTION ESTIMATOR

We will now derive a novel scheme for motion estimation based on the above solution of the observation model for image acquisition. We state that two image blocks under test describe the same physical region if they originate with highest probability from a common underlying block of a higher resolution. By choosing an appropriate set of possible motion matrices  $M^j$ ,  $j = 1, \dots, J$  and solving Equation (1) for  $x$  as in Equation (2) (with  $L = 2$ ) - i.e. constructing  $J$  different SR blocks, one for each possible motion - one may calculate the costs associated with two blocks  $b_{1,k}$  and  $b_{0,l}$  given a testing motion matrix  $M^j$  as:

$$C_{MAP}(b_{1,k}, b_{0,l}, M^j) = (b_{1,k} - DBx)^T (b_{1,k} - DBx) + (b_{0,l} - DBM^j x)^T (b_{0,l} - DBM^j x) + c \sum_{s \in S} \phi_s(x - Nx) \quad (7)$$

In the first term the motion matrix is an identity matrix and can be dropped as we consider motion with respect to  $b_{1,k}$

(and the motion from  $b_{1,k}$  to itself is  $(0, 0)$ ). The matching block in the reference image can now be determined as the block  $b_{0,\tilde{l}}$  which together with the motion matrix  $M^{\tilde{j}}$  fulfils  $(\tilde{l}, \tilde{j}) = \arg \min_{l,j} (C_{MAP})$ . Note that  $b_{0,\tilde{l}}$  describes a large-scale motion and  $M^{\tilde{j}}$  describes a small-scale motion. Fractional pixel accuracy is automatically obtained by choosing appropriate dimensions for the matrices  $D, B, M^j$  and the unknown signal vector  $x$ .

As a byproduct to motion estimation an estimate  $\hat{x}$  for the Super-Resolution image is obtained. Thus, the proposed method can be seen as a combined estimation of motion and a SR image.

In order to illustrate the concept of this novel method a small example will be shown. In Figure (1), two  $8 \times 8$  blocks are

Fig. 1. Motion between two blocks

shown having a simulated displacement of  $(0, -0.5)$ , i.e. half a pixel upwards. Restricting ourselves to half-pixel accuracy there are nine possible motions in the direct neighbourhood which are depicted in Figure (1) (c). Note that in this example  $M^7$  is the true motion.

In Figure (2) the cost function  $C_{MAP}$  for  $K = 5$  iterations of the CG algorithm is displayed using the HMRf image model with  $c = 0.01$  and  $\alpha = 1$  for regularisation. It can be seen that the cost function  $C_{MAP}$  under the assumption of the true motion matrix  $M^7$  returns the lowest costs, matrices close to  $M^7$ , i.e.  $M^6$  and  $M^8$  return acceptable costs whereas matrices far away from  $M^7$  return high costs.

In Figure (3) the nine SR blocks which result as a byproduct to motion estimation and the original image block are shown. It can be seen that under the assumption of the true motion matrix  $M^7$  a very accurate estimate of the original block is obtained. These results support the formulation of a new motion estimation algorithm for fractional pixel accuracy as follows:

1. Choose a penalty function  $\phi_s(x)$  and a regularisation parameter  $c$
2. Choose a set of possible motion matrices  $M^j$  with  $j = 1, \dots, J$
3. For all blocks  $b_{0,l}, l = 0, \dots, L - 1$  in the search area
  - For all motion matrices  $M^j$  with  $j = 1, \dots, J$

Fig. 2. Simulation result:  $C_{MAP}$  vs. Iterations

Fig. 3. Simulation result: Nine resulting SR blocks

- Minimise  $C_{MAP}(b_{1,k}, b_{0,l}, M^j)$  with respect to  $x$  as in (7) using  $K$  iterations of the CG algorithm

4. Set  $(\tilde{l}, \tilde{j}) = \arg \min_{l,j} \{C_{MAP_H}(b_{1,k}, b_{0,l}, M^j)\}$

5. Let  $b_{0,\tilde{l}}$  together with  $M^{\tilde{j}}$  describe the motion vector.

The new motion estimator does not rely on principles such as intensity conservation or block similarity. Images are modeled as being blurred, aliased and noisy versions of an unknown image of higher resolution. Consequently, block dissimilarity which occurs due to the aforementioned disturbing factors is part of the observation model and can be dealt with by using SR techniques.

## 5. SIMULATION RESULTS

In Tables 1 and 2, simulation results of our motion estimator compared with the classical block matcher using the SAD distance measure for different noise levels are shown. The first frames of the 'Mobile' and 'Foreman' sequence (CIF format) have been chosen for the simulation setup. They have been shifted, blurred and downsampled, modelling the point spread function of the camera as an averaging function to create two images of lower resolution having a spatial displacement of  $(0.5, 0.5)$ . Furthermore i.i.d. zero-mean Gaussian noise with

variance  $\sigma_\eta^2$  has been added to model the CCD sensor noise. The vector field shall be estimated with halfpel accuracy. The block size has been chosen as  $4 \times 4$ , the search range equals 4 which results in 1596 blocks with 81 motion vector possibilities for each block. For halfpel accuracy the classical block matcher needs an interpolated image, consequently we have chosen a 6 tap FIR interpolation filter [7] approaching an ideal interpolation filter. Its weights are  $\frac{1}{32}[1, -5, 20, 20, -5, 1]$  which results in more accurate motion estimates compared to classical schemes such as the bilinear or bicubic interpolation. Our motion estimator uses  $c = 0.01$  and  $\alpha = 1$  which we found gave good performance. Optimisation is done by using the CG algorithm (GMRF) or the nonlinear CG algorithm (HMRF and DEMRF) with 3 iterations. 100 Monte-Carlo simulations were conducted. The percentage of correctly detected motion vectors has been chosen as a quality measure. It can be seen that our method outperforms the clas-

$\sigma_\eta$	0	1	2	3	4	5

sical block matcher providing a more precise estimated vector field. Furthermore the usage of a more accurate image model (HMRF or DEMRF instead of GMRF) also has a positive effect on the quality of the vector field. However due to the nonlinear optimisation, using the HMRF or DEMRF model is very computationally expensive. Our motion estimator using the GMRF is about 10 times more complex compared to the very simple SAD block matcher, whereas it is about 25 times more complex when using the HMRF or DEMRF model.

Although this work has mainly been focused on motion estimation, the fact that a SR image is obtained simultaneously is of high importance as it overcomes the interdependency problem in SR image reconstruction [1]. In Figure (4) (a) a part of the Super-Resolution image of the 'Mobile' sequence which was obtained as a byproduct to motion estimation is shown. In comparison, Figure (4) (b) shows the same part of the image obtained by using the 6 tap FIR interpolation filter. An improvement in image quality is visible, the Super-Resolution image provides more details than the one obtained by using a classical interpolation scheme. We expect the pro-

posed method to be of interest in the area of Super-Resolution, especially when no *a priori* motion estimates are available. This will be a topic of future research.

**Fig. 4.** SR image obtained as a byproduct

## 6. CONCLUSIONS

A new motion estimation scheme is presented that jointly optimises the motion vector field and a high-resolution reference image. For this purpose and in order to attenuate aliasing and noise, an observation model for the image acquisition process is applied and a Maximum A Posteriori (MAP) optimisation is performed, using Markov Random Field image models for regularising the optimisation problem. The new motion estimation scheme provides superior results compared to classical block matching schemes. A super-resolution image can be obtained as a byproduct to motion estimation. Further improvements are expected when choosing the regularisation parameter and penalty functions adaptively with respect to noise and parameters of the image model.
