Control of the Double-Linked Trident Snake Robot
based on the Analysis of its Oscillatory Dynamics

Masato ISHIKAWA and Takahiro FUJINO

Abstract—In this paper, we propose a new approach to the locomotion control of the trident snake robot, focusing on its “double-linked” case where the robot is composed of a triangular body and three branches of double-linked snake-like legs. Originally, this robot was proposed by the authors as a novel example of nonholonomic mobile robot. This robot is quite interesting from a theoretical point of view; the well-known LARC (Lie Algebra Rank Condition) for its nonlinear controllability has a unique structure that it contains two ‘generator’ vector-fields and higher order Lie brackets, which makes its control problem extremely challenging. In this paper, for this difficult control problem, we first propose a design algorithm which partially achieves the desired locomotion. Then we discover that the resulting motion may or may not be a stable limit cycle, depending on the eigenvalues of the corresponding discrete-time dynamics on its Poincaré map. Finally, we propose a full controller design by combining the stable limit cycles. The validity of the proposed idea is examined by numerical simulations.

I. INTRODUCTION

The trident snake robot is a novel kind of wheeled mobile robot proposed by the authors [1]. This robot is composed of three branches of serial links and a root block, where the three branches are connected to the root block at center, just like a three-pointed star. Each branch is the same as a conventional snake-like robot: i.e., every link has a passive wheel and all the joints are actuated.

This is quite interesting from a theoretical point of view since the well-known LARC (Lie Algebra Rank Condition, given by Chow’s theorem[2]) for its nonlinear controllability has a unique structure (given by eq. (10)). It contains two ‘generator’ vector-fields as well as higher order Lie brackets, which makes the control problem extremely challenging.

The locomotion principle of the trident snake has been clarified for the single-linked case, by analyzing its controllability structure and corresponding holonomy [3]. Now we proceed to tackle with the double-linked case. Unlike 1-link model, the controllability structure of double-linked model is composed of higher order Lie brackets, whose controllability structure is quite complicated. It also has some physical advantages to the 1-link model, e.g., it seldom falls into singular posture, and each wheel supports less load because the contact force is distributed to larger numbers of wheels.

In this paper, for this difficult control problem, we first propose a design algorithm which partially achieves the desired locomotion utilizing the principle of holonomy. Then we discover that the resulting motion may or may not be a stable limit cycle, depending on the eigenvalues of the corresponding discrete-time dynamics on its Poincaré map. Finally, we propose a full controller design by incorporating the stable limit cycles. Note that, among a lot of studies on nonholonomic motion planning ([4], [5], [6]), gait generation and analysis ([7], [8], [9]), an advantage of the proposed method is to focus on the stability of oscillations, and to utilize a relatively simple (first-order) gait to deal with complicated (more than second-order) controllability structure.

This paper is organized as follows. Section II introduces the symbol definitions and the kinematic model of the robot. In Section III, we give its controllability analysis and a fundamental control principle based on the controllability structure and the holonomy generation (so-called Lie bracket motion). The control algorithm for translational locomotion is proposed in Section IV, followed by the shape control (rearrangement of the robot’s shape without changing its position) proposed in Section V. Section VI concludes the paper.

II. MODELING OF THE TRIDENT SNAKE ROBOT

The following symbols are used throughout the paper: $\mathbb{R}$ denotes the set of all real numbers, $\mathbb{Z}$ denotes the set of all integers, $\mathbb{N}$ denotes the set of all natural numbers and $\mathbb{N}_0 := \mathbb{N} \cup \{0\}$ denotes the nonnegative integers. Lie bracket of any two vector-fields $f(\xi)$ and $g(\xi)$ is given by

$$[f, g](\xi) := \frac{\partial g}{\partial \xi} f(\xi) - \frac{\partial f}{\partial \xi} g(\xi).$$

A. Kinematics of the Robot

Fig. 1 illustrates the overview of the trident snake robot placed on the flat plane. In the middle of its body, the root
block of the robot is an equilateral triangular plate with three actuated joints at its vertices.

The robot has three branch legs as well, which are connected to the root block via the joints. Each branch is composed of serial double-link with an actuator at its 'hinge' joint. Each link has a passive wheel on its center, which is assumed not to slip, nor slide sideways. This implies that the motion of each wheel is constrained to parallel translation along the link or spin about its vertical axis.

We assume that the radius of the triangle (the distance between its center and a vertex) is the unit length and all the links are twice as long as the unit, thus the distance between a wheel and its adjacent joint is 1.

The position of the robot is characterized by the coordinates \((x, y)\) of the center \(P\) of the root block. The front face of the robot is supposed to be the joint \(\phi_{21}\), and the orientation of the robot is characterized \(\theta_0\). The configuration vector of the robot is

\[
w := [x, y, \theta_0]^T \in SE(2)
\]

Let \(\phi_{ij}\) denote the \(j\)-th joint of the \(i\)-th branch. The link between the joints \(\phi_{ij}\) and \(\phi_{ij+1}\) is called the link-(\(i, j\)). Now we gather all the 'root' angles into \(\phi_1\), and all the 'hinge' angles into \(\phi_2\), as follows:

\[
\phi_1 := [\phi_{11}, \phi_{21}, \phi_{31}]^T
\]

\[
\phi_2 := [\phi_{12}, \phi_{22}, \phi_{32}]^T
\]

Finally, we combine \(\phi_1\) and \(\phi_2\) into the shape vector \(\phi\):

\[
\phi := [\phi_1, \phi_2]^T
\]

Considering the nonholonomic constraints concerning the non-slide-slip condition of the wheels, the kinematics of this robot is described as follows:

\[
A(\phi)R_{\theta_0}^T w = B(\phi)\dot{\phi}
\]  \hspace{1cm} (1)

See [3] for the detail of its derivation. Here \(R_{\theta_0}\) is the homogeneous transformation matrix on \(SE(2)\):

\[
R_{\theta_0} = \begin{bmatrix}
\cos \theta_0 & -\sin \theta_0 & 0 \\
\sin \theta_0 & \cos \theta_0 & 0 \\
0 & 0 & 1
\end{bmatrix}
\]

implying the rotation of the configuration \(w\) counterclockwise by \(\theta_0\). \(A(\phi) \in \mathbb{R}^{6 \times 3}, B(\phi) \in \mathbb{R}^{6 \times 6}\) are matrix-valued function of the shape \(\phi\), while \(R_{\theta_0}\) depends only on the configuration \(w\).

B. State Equation

Now we are ready to convert the kinematics equation into the nonlinear state equation. We define the state vector of the robot as

\[
\xi := [\phi, w]^T
\]  \hspace{1cm} (2)

while the dimension of state variables is 9. Since the number of nonholonomic constraints is 6 (which equals to the number of the wheels), the velocity \(\xi\) is confined in a three-dimensional (tangent) subspace at every instance, as far as kinematics is concerned. From control point of view, this implies that we may have only 3 control parameters to specify the velocity \(\xi\), nevertheless the number of active joints is 6. In this paper, we derive two forms of state equations, depending on the choice of control inputs. We take the base velocity \(\dot{w}\) as the control input in the first case, while it is the angular velocity of the root joints \(\dot{\phi}_1\) in the second case. Both cases are essentially equivalent to each other under proper input transformation.

Case 1: Let \(u = [x, y, \theta_0]\).

From (1), we obtain following state equation

\[
\begin{bmatrix}
\dot{\phi}_1 \\
\dot{\phi}_2 \\
\dot{\xi}
\end{bmatrix} = \begin{bmatrix}
B(\phi)^{-1}A(\phi)R_{\theta_0}^T \\
I_3
\end{bmatrix} u
\]  \hspace{1cm} (3)

where \(I_3\) is 3 × 3 identity matrix. Then we can rewrite it in the following form

\[
\dot{\xi} = g_1(\xi)u_1 + g_2(\xi)u_2 + g_3(\xi)u_3
\]  \hspace{1cm} (4)

where \(g_1 \in \mathbb{R}^{9 \times 1}, g_2 \in \mathbb{R}^{3 \times 1}, g_3 \in \mathbb{R}^{9 \times 1}\) are smooth vector-fields.

Case 2: Let \(u = [\phi_{11}, \phi_{21}, \phi_{31}]\).

We divide the \(6 \times 6\) matrix \(B(\phi)\) into following block matrix

\[
B(\phi) = [B_1(\phi) \ B_2(\phi)]
\]  \hspace{1cm} (5)

where \(B_1(\phi) \in \mathbb{R}^{6 \times 3}, B_2(\phi) \in \mathbb{R}^{6 \times 3}\). Using (5), kinematics equation (1) transforms as follows

\[
[-B_2(\phi) \ A(\phi)R_{\theta_0}^T] \begin{bmatrix}
\dot{\phi}_1 \\
\dot{\phi}_2 \\
\dot{\xi}
\end{bmatrix} = B_1(\phi)\dot{\phi}_{11}
\]  \hspace{1cm} (6)

Then, we can obtain following state equation

\[
\begin{bmatrix}
\dot{\phi}_1 \\
\dot{\phi}_2 \\
\dot{\xi}
\end{bmatrix} = \begin{bmatrix}
I_3 \\
[-B_2(\phi) \ A(\phi)R_{\theta_0}^T]^{-1}B_1(\phi)
\end{bmatrix} u
\]  \hspace{1cm} (7)

Now we rewrite it in the vector-field form

\[
\dot{\xi} = h_1(\xi)u_1 + h_2(\xi)u_2 + h_3(\xi)u_3
\]  \hspace{1cm} (8)

where \(h_1 \in \mathbb{R}^{9 \times 1}, h_2 \in \mathbb{R}^{9 \times 1}, h_3 \in \mathbb{R}^{9 \times 1}\) are smooth vector-fields. In summary, both state equations (4) and (8) are 3-input and 9-state drift-free (or symmetric affine) systems.

Remark 1: From now on, we sometimes omit the arguments \(\xi\) from the vector-fields \(g(\xi), h(\xi)\). In addition, we use the notation \(g^w, h^w \in \mathbb{R}^{3 \times 1}, g^{\phi, 1}, h^{\phi, 1} \in \mathbb{R}^{3 \times 1}, g^{\phi, 2}, h^{\phi, 2} \in \mathbb{R}^{3 \times 1}\) to indicate the components of the vector-fields, corresponding velocities of the base, angular velocities of the root and angular velocities of the hinge joint respectively, as follows.

\[
g = \begin{bmatrix}
g^{\phi, 1} \\
g^{\phi, 2} \\
g^w
\end{bmatrix}, \quad h = \begin{bmatrix}
h^{\phi, 1} \\
h^{\phi, 2} \\
h^w
\end{bmatrix}
\]  \hspace{1cm} (9)
III. CONTROLLABILITY ANALYSIS AND THE FUNDAMENTAL CONTROL PRINCIPLE

A. Controllability Analysis

Consider the set of input vector-fields $G := \{g_1, g_2, g_3\}$. Controllability of symmetric affine systems is completely characterized by controllability Lie algebra, i.e., the smallest distribution $\mathcal{G}$ that contains $G$ and closed under the Lie bracket operation. The system is controllable if and only if the dimension of $\mathcal{G}$ coincides with the dimension of state space at all points. This condition is known as LARC(Lie Algebra Rank Condition) given by Chow’s theorem.[2]

The controllability Lie algebra of the double-linked model is obtained by calculating Lie brackets as follows. Let us compute the first-order Lie brackets

$$g_{12} := [g_1, g_2], \quad g_{23} := [g_2, g_3], \quad g_{31} := [g_3, g_1].$$

and some of the second-order Lie brackets

$$g_{121} := [[g_1, g_2], g_1], \quad g_{122} := [[g_1, g_2], g_2],$$

$$g_{311} := [[g_3, g_1], g_1].$$

By complicated but straightforward computation of Lie bracketing, we can check that

$$\bar{G} := \text{span}\{g_1, g_2, g_3, g_{12}, g_{23}, g_{31}, g_{121}, g_{122}, g_{311}\}$$

and $\bar{G}(\xi)$ spans full tangent space $\mathbb{R}^9$ for almost all $\xi$, except some singular postures\(^1\), thus the state equation (4) is controllable. Likewise, starting from the set of input vector-fields $H := \{h_1, h_2, h_3\}$, we can also conclude that the state equation (8) is controllable.

B. Periodic Input Design via Exterior Product Equation

We propose a new control design method to realize desired locomotion of the robot by periodic inputs, which moves the state variables to subspace spanned by the first order Lie brackets $g_{12}, g_{23}, g_{31}$.

First, suppose that the control input $u \in \mathbb{R}^{3 \times 1}$ is parameterized by the vector $\bar{u} \in \mathbb{R}^2$ and the matrix $K \in \mathbb{R}^{3 \times 2}$ as follows:

$$u = \begin{bmatrix} K_{11} & K_{12} \\ K_{21} & K_{22} \\ K_{31} & K_{32} \end{bmatrix} \bar{u}$$

where $K_{1i}, K_{2i} \in \mathbb{R}, i = 1, 2, 3$. Geometrically, this implies that $u$ is restricted to the subspace spanned by $K_1 := [K_{11}, K_{12}, K_{13}]^T$ and $K_2 := [K_{21}, K_{22}, K_{23}]$ with the coefficients $\bar{u}_1, \bar{u}_2$ (See Fig. 2).

When the input $u$ is restricted to this form, the state equation can be reduced to

$$\dot{\xi} = \begin{bmatrix} g_1 & g_2 \end{bmatrix} \bar{u}$$

where $\bar{g}_1, \bar{g}_2$ are linear combinations of input vector-fields $g_1, g_2, g_3$ as follows.

$$\bar{g}_1 := \sum_{i=1}^{3} K_{1i} g_i, \quad \bar{g}_2 := \sum_{i=1}^{3} K_{2i} g_i$$

Now suppose to apply the following time-periodic signal to $\bar{u}$:

$$\bar{u} = \begin{bmatrix} \bar{u}_1, \bar{u}_2 \end{bmatrix}^T = \begin{bmatrix} -\epsilon \omega \sin \omega t, \ \epsilon \omega \cos \omega t \end{bmatrix}^T$$

then $\xi_T := \xi(T)$ where $T = 2\pi/\omega$, the state after one cycle, is given by the first-order Lie bracket $[\bar{g}_1, \bar{g}_2]$ as follows:

$$\xi_T = \xi_0 + \pi^2 [\bar{g}_1, \bar{g}_2] + O(\epsilon^3)$$

This formula is called the principle of holonomy, or the area rule[6]. The remainder $O(\epsilon^3)$ tends to be small for high order of $\epsilon$. The net displacement of the state is approximated by

$$\Delta \xi_T := \xi_T - \xi_0 \approx \epsilon^2 [\bar{g}_1, \bar{g}_2]$$

Using the skew-symmetry of Lie bracket operation $([f,g]) = -[g,f])$, we have

$$[\bar{g}_1, \bar{g}_2] = \kappa_{12} g_{12} + \kappa_{23} g_{23} + \kappa_{31} g_{31}$$

$$\kappa_{12} := K_{11} K_{22} - K_{12} K_{21}, \quad \kappa_{23} := K_{21} K_{32} - K_{22} K_{31}, \quad \kappa_{31} := K_{31} K_{12} - K_{32} K_{11}.$$

$$\kappa := [\kappa_{23}, \kappa_{31}, \kappa_{12}]^T$$

satisfies the following exterior product equation:

$$\kappa = K_1 \times K_2$$

Conversely, given $\kappa$, we can always find $K_1$ and $K_2$ which satisfy (18) though the solution is not unique. The corresponding control input is given by (11) and (14).

C. Approximate equilibrium and analysis of its stability

In this subsection, we consider the periodic dynamics of the system (15) under above pre-specified input design method. Let us approximate displacement of the state by focusing on the influence of first-order Lie brackets. Suppose $\Delta \xi_T$ is given by the approximated formula (16). Then, a state $\xi^*_T$ that satisfies

$$[\bar{g}_1, \bar{g}_2] (\xi^*_T) = 0$$

is called an approximate equilibrium of first order.

Next, let us discretize the original continuous-time system with the interval $T$:

$$\xi[k] := \xi(kT), \quad k \in \mathbb{N}_0, \quad T = 2\pi/\omega$$

\(^1\)The singularity occurs when $A(\phi)$ fails to be full column-rank. See [3] for detailed issue on the singularity.
Then (15) and (16) are expressed by following equation.
\[ \xi[k + 1] = \xi[k] + \Delta(\xi[k]) \]
\[ \Delta(\xi[k]) \sim = \pi^2 \left[ g_1, g_2 \right] \]
Finally, linearization of the system (21) in a vicinity of \( \xi^* \) is obtained as follows.
\[ \xi[k + 1] - \xi^* = \left( I_9 + \frac{\partial \Delta(\xi[k])}{\partial \xi[k]} \right) \xi[k] - \xi^* \]
where \( I_9 \in \mathbb{R}^{9 \times 9} \) is 9 × 9 identity matrix. 
\( \xi^* \) is a locally asymptotically stable equilibrium of the Poincaré map if the spectral radius of
\[ A := I + \frac{\partial \Delta(\xi[k])}{\partial \xi[k]} \xi[k] = \xi^* \]
is less than 1.

IV. CONTROL FOR TRANSLATIONAL LOCOMOTION
The purpose of translation control is to change \((x, y)\) without changing the other variables: the change of state variables after one cycle \( \Delta \xi \) have to satisfy with
\[ \Delta \xi_T = \left[ 0, 0, 0, 0, 0, 0, \alpha_x, \alpha_y, 0 \right]^T \]
where \( \alpha_x, \alpha_y \) is constant of translation. In translation control, we take the angular velocities of the root joints for control input, so state equation is (8).

A. The Periodic Input Design Based on Analysis of Stability
Now, the orientation of the robot doesn’t change, so without loss of generality, we set \( \theta_0 = 0 \). Firstly, not caring with the change of the hinge joint angle, we find \([ \kappa_{12}, \kappa_{23}, \kappa_{31} ]^T\) to satisfy with \( \Delta w_T = \left[ \alpha_x, \alpha_y, 0 \right]^T \) from following equation:
\[ \begin{bmatrix} \alpha_x \\ \alpha_y \\ 0 \end{bmatrix} = \pi^2 \begin{bmatrix} h_{12}^{w} (\phi) & h_{23}^{w} (\phi) & h_{31}^{w} (\phi) \end{bmatrix} \begin{bmatrix} \kappa_{12} \\ \kappa_{23} \\ \kappa_{31} \end{bmatrix} \]
where \( h_{12}^{w} (\phi), h_{23}^{w} (\phi), h_{31}^{w} (\phi) \) depends on only the root joint angle \( \phi_{1} \). Furthermore, rank\([ h_{12}^{w} (\phi), h_{23}^{w} (\phi), h_{31}^{w} (\phi) ]^T = 3 \) for arbitrary \( \phi_{1} \), so we can obtain \( h_{12}^{w} (\phi), h_{23}^{w} (\phi), h_{31}^{w} (\phi) \) uniquely. Under the pre-specified \( \kappa_{12}, \kappa_{23}, \kappa_{31} \), the change of the hinge joint angle \( \Delta \phi_{2} \) is expressed as
\[ \Delta \phi_{2} \sim \pi \epsilon \left[ h_{12}^{\phi_{2}} (\phi) & h_{23}^{\phi_{2}} (\phi) & h_{31}^{\phi_{2}} (\phi) \right] \]
Here, \( \phi_{2}^* \) satisfying with \( \Delta \phi_{2} = 0 \) is the approximate equilibrium of first-order for \( \phi_{2} \) under pre-specified \( \phi_{1} \) and \( \kappa \). Furthermore, analyzing the stability of \( \phi_{2}^* \), we can know the convergent shape of the hinge joint angle for translation.

**Procedure 1** Control input design for translation

Step 1 From (24), set \( \kappa_{12}, \kappa_{23}, \kappa_{31} \) for pre-specified \( \phi_{1} \).

Step 2 Solve \( \Delta \phi_{2} = 0 \) in (25) to obtain the approximate equilibrium of first-order: \( \phi_{2}^* \) and analyze the stability of \( \phi_{2}^* \) to know the convergent shape of the hinge joint angle for translation.

Step 3 Solve \( K_1, K_2 \) in (??) and (??).

Step 4 Determine control input \( u \) from (11).

B. Simulation

We set \( \epsilon = 0.2, \omega = 1 \) and \( \alpha_x = 1, \alpha_y = 0 \). In the Step 1, we obtain \( \kappa_{12} = 0.34, \kappa_{23} = -0.34, \kappa_{31} = 0 \) from (24) for initial shape \( \phi_{0} = \left[ \frac{\pi}{2}, 0, -\frac{\pi}{2}, 0, 0 \right]^T \). In the next Step 2, we set \( K_1 = [0, -0.69, 0]^T, K_2 = [0.49, 0, 0.49]^T \), then the control input for translate from (24) is
\[ \begin{align*}
  u_1 &= 0.49 \cos t \\
  u_2 &= 0.69 \sin t \\
  u_3 &= 0.49 \cos t
\end{align*} \]
one cycle configuration vector existing at the vicinity of the approximate equilibrium under pre-specified the hinge joint angles is expressed as follows:

\[ \theta \]

The purpose of shape control is to change an initial shape \( \phi[0] \) to arbitrary reference shape \( \phi^{ref} \) without changing the configuration vector \( w \): the change of state variables after one cycle \( \Delta \xi_T \) have to satisfy with

\[ \Delta \xi_T = \begin{bmatrix} \phi^{ref}_{11}, \phi^{ref}_{21}, \phi^{ref}_{31}, \phi^{ref}_{12}, \phi^{ref}_{22}, \phi^{ref}_{32}, x[0], y[0], \theta[0][0] \end{bmatrix}^T \]

where \( x[0], y[0], \theta[0][0] \) is an initial shape. In shape control, we take the velocities of the base for control input, so state equation is (4).

V. CONTROL FOR SHAPE RERANGEMENT

The purpose of shape control is to change an initial shape \( \phi[0] \) to arbitrary reference shape \( \phi^{ref} \) without changing the configuration vector \( w \): the change of state variables after one cycle \( \Delta \xi_T \) have to satisfy with

\[ \Delta \xi_T = \begin{bmatrix} \phi^{ref}_{11}, \phi^{ref}_{21}, \phi^{ref}_{31}, \phi^{ref}_{12}, \phi^{ref}_{22}, \phi^{ref}_{32}, x[0], y[0], \theta[0][0] \end{bmatrix}^T \]

where \( x[0], y[0], \theta[0][0] \) is an initial shape. In shape control, we take the velocities of the base for control input, so state equation is (4).

A. The Existence of Stable Equilibrium and The Definition of Invariant Sets

The orientation of the robot doesn’t change, so without loss of generality, we set \( \theta[0] = 0 \). Now, \( g^{\phi}_{12}, g^{\phi}_{23}, g^{\phi}_{31} \) are constant vectors and are linear independent. Therefore, we can set a constant vector \( [k^{\phi}_{12}, k^{\phi}_{23}, k^{\phi}_{31}]^T \) to realize arbitrary change of shape \( \Delta \phi[1] \) from following equation:

\[ \Delta \phi[1] = \pi \epsilon^2 (k^{\phi}_{12} g^{\phi}_{12} + k^{\phi}_{23} g^{\phi}_{23} + k^{\phi}_{31} g^{\phi}_{31}) \]

Then, under the pre-specified \( [k^{\phi}_{12}, k^{\phi}_{23}, k^{\phi}_{31}]^T \), the change of the hinge joint angles is expressed as follows:

\[ \Delta \phi[2] \equiv \pi \epsilon^2 (k^{\phi}_{12} g^{\phi}_{12} + k^{\phi}_{23} g^{\phi}_{23} + k^{\phi}_{31} g^{\phi}_{31}) \]

Fig. 3 and Fig. 4 show the simulation results. In Fig. 3, (a) shows the time response of the configuration of the robot: \( x, y, \theta \). And (b) and (c) show the time response of the root joint angle: \( \phi_{11}, \phi_{21}, \phi_{31} \) and the hinge joint angle: \( \phi_{12}, \phi_{22}, \phi_{32} \) respectively. From (a), we can confirm that \( y \) and \( \theta \) after one cycle return to initial value, but by contrast, \( x \) moves along \( x \)-axis to the minus direction. (b) shows that the root joint angle \( \phi_1 \) doesn’t change periodically. This is because we take \( \phi_1 \) to control input and apply it periodic function. Furthermore, we can confirm that the hinge joint angle \( \phi_2 \) converges to a specific value, which is attributed to the stability of the approximate equilibrium of first-order \( \phi^{\#}_{2} := [\phi^{\#}_{12}, \phi^{\#}_{22}, \phi^{\#}_{32}]^T = [1.05, 0, -1.05]^T \).

Now, we define following set \( M_1 \) for \( (\phi_1, \phi_2) \).

\[ M_1 := \{ (\phi_1, \phi_2) \mid \phi_2 = \phi^{\#}_{2} \} \]

\( M_1 \) is an invariant set because if \( (\phi_1[\ell], \phi_2[\ell]) \in M_1 \) for \( \forall \ell \in \mathbb{N}_0 \), then \( (\phi_1[\ell + 1], \phi_2[\ell + 1]) \in M_1 \) for \( \forall n \in \mathbb{N} \). Next, we define following set \( M_2 \) for \( (\phi_1, \phi_2) \).

\[ M_2 := \{ (\phi_1, \phi_2) \mid \phi_1 = \phi^{ref}_{11} - D_k(\phi^{ref}_{22}, \phi_2), k \in \mathbb{Z} \} \]

where \( D_k(\phi^{ref}_{22}, \phi_2) \) is the amount of displacement of \( \phi_1 \) which we control \( \phi_2 \) to \( \phi^{ref}_{22} \) after \( k \) cycles as follows:

\[ D_k(\phi^{ref}_{22}, \phi_2) \equiv \pi \epsilon^2 \sum_{\ell=1}^{k} [g^{\phi}_{12} g^{\phi}_{23} g^{\phi}_{31}] \kappa[\ell] \]

where \( \kappa[\ell] \) can be solved from following equation:

\[ \kappa[\ell] \equiv \frac{1}{\pi \epsilon^2 n} \left[ g^{\phi}_{12}(\phi_2[\ell - 1]) g^{\phi}_{23}(\phi_2[\ell - 1]) g^{\phi}_{31}(\phi_2[\ell - 1]) \right]^{-1}(\phi^{ref}_{22} - \phi^{\#}_{2}) \]

(34) is the design equation for \( \kappa_{12}[\ell], \kappa_{23}[\ell], \kappa_{31}[\ell] \) to control \( \phi_2 \) to \( \phi^{ref}_{22} \) after \( k \) cycles and make the amount of displacement after one cycle equal. In fact, if \( \phi \in M_2 \), then we can control \( \phi_2 \) to \( \phi^{ref}_{22} \) and \( \phi_1 \) to \( \phi^{ref}_{22} \) simultaneously under pre-specified \( k^{\phi}_{12}, k^{\phi}_{23}, k^{\phi}_{31} \) in (34). Furthermore, as long as we set \( k_{12}[\ell], k_{23}[\ell], k_{31}[\ell] \) in (34), if \( (\phi_1[\ell], \phi_2[\ell]) \in M_2 \) for \( \forall \ell \in \mathbb{N}_0 \), then \( (\phi_1[\ell + 1], \phi_2[\ell + 1]) \in M_2 \) for \( \forall n \in \mathbb{N} \), so the set \( M_2 \) is an invariant set.

B. Periodic Input Design Using Invariant Sets

In this section, we describe about the method of control design using \( M_1, M_2 \) effectively. If \( \phi := (\phi_1, \phi_2) \) belongs to \( M_2 \), we can control \( \phi \) to \( \phi^{ref} \) by setting \( k_{12}[\ell], k_{23}[\ell], k_{31}[\ell] \) in (34). Therefore, we have only to
control initial shape \((\phi_1[0], \phi_2[0])\) to \((\phi_1^{M_2}, \phi_2^{M_2})\) \(\in M_2\). Here, we define a following set:

\[
M := M_1 \cap M_2
\]

We can set \(\kappa_{12}, \kappa_{23}, \kappa_{31}\) in (28) to control \(\phi_1[0]\) to \(\phi_1^M \in M\) and under such a \(\kappa_{12}, \kappa_{23}, \kappa_{31}\), it can be expected that \(\phi_2\) converges to the vicinity of \(\phi_2^M\) as Fig. 5 shown. So we can control \(\phi\) to \(\phi^M \in M\) along \(M_1\). Finally, we switch a control method and control \(\phi\) to \(\phi^{\text{ref}}\) along \(M_2\).

[Procedure 2] Control input design for shape control
Step 1 Set \(\kappa_2\) and solve \(\kappa_{[\ell]}(1 \leq \ell \leq k, \ell \in \mathbb{N})\) from (34)
Step 2 Set \(D_k(\phi^{\text{ref}}, \phi^M)\) from (33)
Step 3 Set \(\kappa_{12}, \kappa_{23}, \kappa_{31}\) from (28) and determine control input \(u\) form (22), (22) and (11) to control \(\phi\) to \(\phi^M\)
Step 4 Determine the control input \(u\) from (11) and (18) using \(\kappa_{[\ell]}\) obtained in Step 1, to change \(\phi\) from \(\phi^M\) to \(\phi^{\text{ref}}\).

C. Simulation
We set the initial shape \(\phi_0 = [-0.7, -1.0, -0.8, 2.2, 2.3, 2.2]^T\), the reference shape \(\phi^{\text{ref}} = [0, 0, 0, 0, 0, 0]^T\), \(\epsilon = 0.1\), \(\omega = 1\) and \(\phi_2 = -2.7\). Fig. 6 shows the simulation results at Step 3 and Fig. 7 shows the simulation results at Step 4. Finally, Fig. 8 shows initial posture and final posture of the robot. From Fig. 7, we can confirm that the shape of the robot is controlled to the reference shape.

VI. CONCLUSIONS
In this paper, we proposed a new control method for locomotion control problem of the double-linked trident snake robot. The feature of our proposed method is not to create the behavior corresponding high order Lie brackets which characterize controllability structure of the robot but to use a specific nonlinear dynamics effectively. In the case of this robot, a specific dynamics is the periodical property that some state variables whose behavior can’t be designed directly, the hinge joint angles, converge to a stable cycle under pre-specified control parameter. This proposed idea can be a practical control method not only for this robot but also for such a nonlinear system, whose controllable structure is complicated, as multi-generator system.

ACKNOWLEDGEMENTS
The authors are grateful to Professor Toshiharu Sugie in Kyoto University for his valuable comments and continuous encouragements.
