Learning an Optimal Control Policy for a Markov Decision Process Under Linear Temporal Logic Specifications

Masaki Hiromoto and Toshimitsu Ushio

Abstract—In this paper, we consider an optimal control problem under a qualitative specification such as progress and safety properties for a Markov decision process (MDP) with control costs. This control problem is motivated by the optimal path planning and control of mobile robots. We assume the existence of the uncertainty such as the unknown transition probability in the MDP. Then, we apply reinforcement learning (RL) to the generation of the optimal control policy. We consider the case where the qualitative specification is described by a linear temporal logic (LTL) formula. We construct a deterministic Rabin automaton (DRA) by which we check if the controlled behavior of the MDP satisfies the LTL specification with probability 1. We convert the DRA to a weighted automaton whose weight is determined based on the acceptance conditions of the DRA. Thus, the weighted automaton is used to learn a control policy that satisfies the LTL specification. Then, the control problem considered in the paper is reduced to a reinforcement learning problem with multiple rewards that correspond to the control costs and the weights. To generate the optimal control policy, using the MDP and the weighted automaton, we construct a product MDP with sequentially decision making. The proposed controller consists of a sequential decision making of two steps. At the first step, one learns a minimally restrictive set of actions such that if an action selected at the second step generates runs that do not satisfy the LTL specification, it is eliminated from the set. At the second step, one learns the optimal action that minimizes the discounted sum of the control costs in the set. We also consider an illustrative example to show that the proposed RL based controller can learn an optimal control policy.

I. INTRODUCTION

A temporal logic (TL) has been used to verify reactive and concurrent systems [1]. The TL is an extension of a classical logic and describes temporal properties, that is, properties of state transitions. Recently, in many control applications such as the optimal path planning and control of mobile robots, there has been an increased interest in describing a qualitative control specification by the TL. [2]–[15]. Several control methods have been proposed. In [2], they considered a discrete-time linear time-invariant system under constraints given by a linear temporal logic (LTL) formula and proposed a receding horizon control (RHC) using a finite abstraction of the continuous state set. In [3], the RHC for finite deterministic systems has been studied. On the other hand, for the logical control of discrete event systems (DESs) where a control specification is given by a language, a supervisory control has been studied [16]. In [5], they consider the case where a control specification is given by an LTL, a computational tree logic (CTL), or a CTL* formula and, for each TL formula, proposed a design method for a supervisor such that all infinite words generated by the supervised DES satisfies the TL formula. They use an \(\omega\)-automaton to decide whether the controlled behavior satisfies the TL formula. Such an automaton based approach is often used for the checking the satisfaction of the LTL formula [17]. Safra’s method is a well-known method for the conversion from the LTL formula to a deterministic Rabin automaton (DRA) and uses a non-deterministic Büchi automaton as an intermediate automaton [18]. Recently, however, a novel method for direct conversion from the LTL formula to a DRA has been proposed [19]. The DRA constructed by the novel method has acceptance conditions based on not only states but also transitions and the cardinality of its state set is smaller than that of the DRA by Safra’s method.

In general, when a system is uncertain, that is, the system’s parameters are unknown a priori, the robust control approach is often used when the uncertainty is described in such a way that the unknown parameter is in a given set. In [4], they consider an uncertain Markov decision process (MDP) where each transition probability is in a given uncertain set and proposed a robust controller that satisfies a control specification given by an LTL formula. Recently, learning based control has been proposed as another approach to the design of the controller [20], [21]. A reinforcement learning (RL) based approach is useful for such a situation [22], [23]. The RL is a learning framework that learns a transition probabilities and control cost function of the uncertain MDP and searches an optimal control policy that optimizes an expected discounted sum of the costs through trial and error. In [20], Sadigh et al. considered an uncertain MDP and a control specification given by an LTL formula. They proposed a RL based method for design of a control policy such that the controlled MDP satisfies the LTL formula with probability 1. They constructed a DRA that accepts all words satisfying the formula and computes a product MDP of the MDP and the DRA. Then, to learn the control policy by which the controlled MDP satisfies the LTL formula with probability 1, a reward is assigned to each state of the product MDP in accordance with the acceptance conditions of the DRA. Using the reward, the controller learns an optimal policy such that an expected discounted sum of the rewards on the controlled product MDP is maximized for each state. In [21], Jones et al. considered a control specification described by a signal temporal logic (STL) formula. To the best of our knowledge, a problem to learn a control policy
that optimizes the control cost on the MDP under the LTL formula has not been studied. So, we consider an MDP with control cost for each state and formulate an optimal control problem that has the following two control objectives: The first objective is for the controlled MDP to satisfy the LTL formula with probability 1. The second one is to minimize the expected discounted sum of the control costs. Such a control problem is applicable to the optimal path planning of mobile robots with safety and progress properties.

In this paper, first, we construct a DRA that accepts all and only infinite words satisfying the given LTL control specification. Second, we construct a product MDP of the MDP and the DRA to represent a dynamic control policy that satisfies the control specification. Third, we modify the product MDP in order to apply RL to the design of an optimal control policy. The modified product MDP has a set of reward functions that return a reward for each transition on the modified product MDP in accordance with the acceptance conditions of the DRA. The control action of the modified product MDP is a pair of a pattern and an action, where the pattern is a set of actions. Moreover, we introduce a reward that represents both the satisfaction of the control specification and the minimally restrictiveness of the pattern. Finally, we proposed an algorithm for design of an optimal control policy that consists of a sequential decision making of two steps. At the first decision making, we remove actions by which runs that do not satisfy the LTL control specification. At the second one, we select an action from the pattern selected at the first one such that it minimizes the discounted sum of the costs.

This paper is organized as follows: In Section II, we review an LTL formula and a DRA. In Section III, we formulate an optimal control problem of an MDP with control costs under an LTL control specification. In Section IV, we propose a method to design an optimal policy using RL. In Section V, we consider an illustrative example to show that the proposed algorithm can obtain an optimal control policy. We conclude in Section VI.

II. PRELIMINARY

We review Linear temporal logic (LTL) [1]. We use an LTL formula to describe a control specification. An LTL formula is recursively defined over a finite fixed set of atomic propositions \( AP \) as follows.

- An atomic proposition \( a \in AP \), the symbol \( \top \), and the symbol \( \bot \) are LTL formulas.
- For given LTL formulas \( \varphi \) and \( \psi \), \( \neg \varphi \), \( \varphi \land \psi \), and \( \varphi \lor \psi \) are LTL formulas, and
- For given LTL formulas \( \varphi \) and \( \psi \), \( X \varphi \), \( F \varphi \), \( G \varphi \), and \( \varphi \Uparrow \psi \) are LTL formulas.

where \( \neg \) is a negation, \( \land \) is a logical conjunction, and \( \lor \) is a logical disjunction. The LTL formula \( \varphi \) is qualitatively evaluated by an infinite word \( w \in (2^AP)^\omega \). The \( i \)th letter of \( \omega \) is denoted by \( \omega[i] \), i.e., \( \omega = \omega[0] \omega[1] \ldots \). The suffix of \( \omega \) starting from the \( i \)th letter is denoted by \( \omega[i] \omega[i+1] \ldots \). We write \( w \models \varphi \) if \( \varphi \) is TRUE for \( w \). We write \( w \not\models \varphi \) if \( \varphi \) is FALSE for \( w \).

Semantics of the formula on the word \( \omega \) is defined inductively as follows.

\[
\begin{align*}
w &\models \top. \quad w \not\models \bot. \\
w &\models a \iff a \in \omega[0]. \\
w &\models \neg a \iff a \not\in \omega[0]. \\
w &\models \varphi \land \psi \iff w \models \varphi \land w \models \psi. \\
w &\models \varphi \lor \psi \iff w \models \varphi \lor w \models \psi. \\
w &\models X \varphi \iff w_1 = \varphi. \\
w &\models F \varphi \iff \exists k \geq 0, w_k \models \varphi. \\
w &\models G \varphi \iff \forall k \geq 0, w_k \models \varphi. \\
w &\models \varphi \Uparrow \psi \iff \exists k \geq 0, \forall l (0 \leq l < k), w_k \models \psi \land w_l \models \varphi. \\
\end{align*}
\]

Intuitively, if \( \varphi \) and \( \psi \) are atomic propositions, \( X \varphi \) is TRUE when \( \varphi \) is TRUE in the next step, \( F \varphi \) is TRUE when \( \varphi \) is TRUE in some steps, \( G \varphi \) is TRUE when \( \varphi \) is TRUE in all steps, and \( \varphi \Uparrow \psi \) is TRUE when \( \psi \) becomes TRUE. Several control specifications such as liveness properties \( GF \varphi \), stability properties \( FG \varphi \) and safety properties \( \neg \varphi \) are described by the LTL formulas.

We introduce a deterministic Rabin automaton (DRA) [19]. The DRA \( R \) is described by \((Q, q_0, \Sigma, \delta, Acc)\), where \( Q \) is a finite and non-empty set of states, \( q_0 \in Q \) is an initial state, \( \Sigma \) is a finite set of input alphabets, \( \delta : Q \times \Sigma \rightarrow Q \) is a transition function, \( Acc = \{Acc_i\}_{i=1}^{n_{Acc}} \) is a set of acceptance conditions, \( Acc_i = (S_i, T_i) \) for each \( i = 1, \ldots, n_{Acc} \), \( S_i \subseteq Q \) is a set of non-acceptance states, \( T_i = (G_i, B_i) \subseteq \Delta \times \Delta \), \( \Delta = \{(q, \nu, q') \in Q \times 2^Q \mid \delta(q, \nu) = q'\} \) is a transition relation, \( G_i \) is a set of acceptance transitions, and \( B_i \) is a set of non-acceptance transitions. We consider two kinds of infinite sequences in the DRA for the input word \( w \in (\Sigma)^\omega : r_q \in Q^\omega \) and \( r_d \in \Delta^\omega \) defined by \( r_q = r_q[0] r_q[1] \ldots \) with \( r_q[i] = \delta(r_q[i-1], \omega[i-1]) \) \((r_q[0] = q_0)\) and \( r_d = r_d[0] r_d[1] \ldots \) with \( r_d[i] = (r_d[i], \omega[i], r_d[i+1]) \in \Delta \). We call the pair \( r = (r_q, r_d) \) the run of \( R \) over \( w \). For each sequence, let \( inf(r_i) \) be a set of elements that appear infinitely often in the sequence.

\[ inf(r_i) = \{ \hat{i} \mid \hat{i} = r_i[i] \text{ for infinitely many } i \text{'s} \} \text{ for } l = q, d. \]

Note that \( inf(r_q) \) and \( inf(r_d) \) are nonempty sets because both \( Q \) and \( \Delta \) are finite sets. The run \( r = (r_q, r_d) \) is accepted by \( Acc \) if there exists \( i \in \{1, \ldots, n_{Acc}\} \) such that

\[
inf(r_q) \cap S_i = \emptyset \quad \text{and} \quad inf(r_d) \cap G_i \neq \emptyset \quad \text{and} \quad inf(r_d) \cap B_i = \emptyset. \quad (1)
\]

For each LTL formula \( \varphi \) over \( AP \), let \( R_\varphi \) be a DRA with a finite set of input alphabets \( \Sigma = 2^AP \) that accepts all and only infinite words over \( AP \) that satisfy \( \varphi \).

III. PROBLEM FORMULATION

We consider a plant modeled by a labeled Markov decision process (MDP) \( M = (S, \Lambda, A, P, s_0, AP, L, g) \), where \( S \) is a finite and non-empty set of states of the plant, \( A = \{a_1, \ldots, a_{n_A}\} \) is a finite and non-empty set of actions (controls), \( \Lambda : S \times A \times S \rightarrow [0, 1] \) is a function that represents a set of available actions at each state, \( P : S \times A \rightarrow \{0, 1\} \) is a transition probability function.
such that $\sum_{s' \in S} P(s, a, s') = 1$ for all $s \in S$ and $a \in A(s)$, $s_0 \in S$ is an initial state, $AP$ is a set of atomic propositions, $L : S \to 2^{AP}$ is a labeling function, $q : S \times A \to \mathbb{R}_{\geq 0}$ is a control cost function, and $\mathbb{R}_{\geq 0}$ denotes the set of non-negative real numbers. Note that the labeling function $L$ returns atomic propositions that are TRUE at the state. In the following, a subset $\pi$ of $A$ will be called a pattern.

We also consider a control specification described by an LTL formula $\varphi$. Then, we construct a DRA $R_{\varphi} = (Q, q_0, 2^{AP}, \delta, Acc)$ that accepts all and only words satisfying $\varphi$. In order to check $\varphi$’s satisfiability for a run on $M$, we introduce a product MDP $M_{\varphi} = (S_{\times}, A_{\times}, P_{\times}, s_{0\times}, Acc_{\times}, g_{\times})$ of $M$ and $R_{\varphi}$ with the same action set $A$ as that of $M$, where:

- $S_{\times} = S \times Q$ is a set of states,
- $A_{\times} : S_{\times} \to 2^A$ is a function such that $A_{\times}(s_x) = A([s_x]_q) \subset A$ is a set of actions available at the state $s_x = (s, q) \in S_{\times}$, where $[\cdot]_q : S \times Q \to S$ is a projection function defined by $[s_x]_q = s$,
- $P_{\times} : S_{\times} \times A \times S_{\times} \to [0, 1]$ is a probability function defined as:

$$P_{\times}(s_x, a, s'_x) = \begin{cases} P([s_x]_q, a, [s'_x]_q) \\ 0 \\ \end{cases}$$

if $[s'_x]_q = \delta([s_x]_q, L([s'_x]_q))$, otherwise,

where $[\cdot]_q : S \times Q \to Q$ is a projection function defined by $[s_x]_q = q$ for $s_x = (s, q)$,
- $s_0\times = (s_0, \delta(q_0, L(s_0))) \in S_{\times}$ is an initial state,
- $Acc_{\times} = \{Acc^i\}_{i=1}^{n_{Acc}}$ is a set of acceptance conditions, for each $i = 1, \ldots, n_{Acc}$, $Acc^i = (S_i^{\times}, T_i^{\times})$ and $T_i^{\times} = (G_i^{\times}, B_i^{\times})$ are defined as:

$S_i^{\times} = \{s_{\times} \mid [s_x]_q \in S_i\}$,
$G_i^{\times} = \{(s_{\times}, s'_{\times}) \mid ([s_x]_q, L([s'_{\times}]_q), [s'_{\times}]_q) \in G_i\}$,
$B_i^{\times} = \{(s_{\times}, s'_{\times}) \mid ([s_x]_q, L([s'_{\times}]_q), [s'_{\times}]_q) \in B_i\},$

and

$g_{\times}(s_{\times}, a) = g([s_x]_q, a)$ is a control cost function.

$P_{\times}(s_x, a, s'_x)$ is a probability such that the transition from $[s_x]_q$ to $[s'_x]_q$ in $M_{\varphi}$ is caused by the occurrence of the action $a$ and the transition from $[s_x]_q$ to $[s'_x]_q$ in $R_{\varphi}$ is caused by the occurrence of the set of atomic propositions $L([s'_x]_q)$. Thus, we define that $[s_0\times]_q$ is not $q_0$ but $\delta(q_0, L(s_0))$.

We consider a control policy $d : S_{\times} \to A$ in $M_{\varphi}$, which is a dynamic policy in $M$. In the following, the control policy will be called the policy for short. The controlled $M_{\varphi}$ by $d$ is described by a Markov chain(MC) $M_d^{\varphi} = (S_{\times}, s_{0\times}, P_{\times}, g_{\times}^d)$, where $p : S_{\times} \times S_{\times} \to \mathbb{R}_{\geq 0}$ is a transition probability function such that $p(s_{\times}^+, \delta(s_{\times}, d(s_{\times})))$ for all $s_{\times} \in S_{\times}$, $T = \{(s_{\times}, s'_{\times}) \mid p(s_{\times}, s'_{\times}) > 0\}$ is a set of transitions, and $g_{\times}^d(s_{\times}, a, d(s_{\times}))$ is a control cost function of the policy $d$. We define a run $r_{d, \varphi}^x = (r_{d, \varphi}^0, r_{d, \varphi}^1, \ldots)$ on $M_d^{\varphi}$ by $r_{d, \varphi}^0 = s_{0\times}$ and $r_{d, \varphi}^{i+1} = r_{d, \varphi}^i \cup \{(s_{\times}^i, a_{\times}, s_{\times}^{i+1}) \mid a_{\times} \in A_{\times}(s_{\times}^i), p(s_{\times}^i, a_{\times}, s_{\times}^{i+1}) > 0\}$ for each $i$ and $d_{\times}^i = s_{\times}^i$ and $d_{\times}^i = d_{\times}^i \cup \{(s_{\times}^i, a_{\times}) \mid a_{\times} \in A_{\times}(s_{\times}^i), p(s_{\times}^i, a_{\times}, s_{\times}^{i+1}) > 0\}$ for each $i$ and $d_{\times}^i = s_{\times}^i$ and $d_{\times}^i = d_{\times}^i \cup \{(s_{\times}^i, a_{\times}) \mid a_{\times} \in A_{\times}(s_{\times}^i), p(s_{\times}^i, a_{\times}, s_{\times}^{i+1}) > 0\}$ for each $i$.

Based on (1), we introduce the following definition.

**Definition 1:** Let $M_d^{\varphi}$ be an MC. We say that $M_d^{\varphi}$ satisfies $\varphi$ with probability 1 if $\inf\{r_{d, \varphi}^i) \cap S_i^\varphi = \emptyset \land \inf\{r_{d, \varphi}^i) \cap G_i^\varphi \neq \emptyset \land \inf\{r_{d, \varphi}^i) \cap B_i^\varphi = \emptyset\} = 1$. Let $D$ be a set of policies $d$ by which $M_d^{\varphi}$ satisfies $\varphi$ with probability 1. We define a discounted sum of the control costs under the policy $d$ after a state $r_{d, \varphi}^i=q_0$ as $t$ follows.

$$R_d^t = \sum_{i=0}^{\infty} \gamma^i r_{d, \varphi}^i(t + i + 1),$$

where $\gamma \in [0, 1)$ is a discount rate. We consider a state value function $V_d : S_{\times} \to \mathbb{R}_{\geq 0}$ for $M_d^{\varphi}$ given by

$$V_d(s_{\times}) = \inf_{d \in D} R_d^0 \mid r_{d, \varphi}^0(t) = s_{\times}$$

$$= \sum_{s'_{\times} \in S_{\times}} p(s_{\times}, s'_{\times}) V_d(s'_{\times}) + \gamma \inf_{d \in D} R_d^{t+1} \mid r_{d, \varphi}^{t+1}(t) = s_{\times}, r_{d, \varphi}^t(t + 1) = s'_{\times}$$

$$= \sum_{s'_{\times} \in S_{\times}} p(s_{\times}, s'_{\times}) [g_{\times}^d(s'_{\times}) + \gamma V_d(s'_{\times})].$$

Our objective is to design an optimal policy $d^* \in D$ such that for all $s_{\times} \in S_{\times}$, $V_d^*(s_{\times}) = \min_{d \in D} V_d(s_{\times})$. In other words, for a given LTL control specification $\varphi$, the optimal control policy $d^*$ achieves the minimization of the discounted sum of the control costs under the requirement that the controlled plant $M_d^{\varphi}$ satisfies $\varphi$ with probability 1.

**IV. RL BASED DESIGN OF OPTIMAL POLICY**

We consider a design problem of the optimal control policy under the existence of uncertainty in the plant $M$, that is, the transition probability function $P$ of the plant is unknown. We apply reinforcement learning(RL) to learn the optimal control policy on-line. Recall that the considered optimal control problem has two requirements, that is, the minimization of the discounted sum of the control costs given by the control cost function $q$ and the satisfaction of the LTL control specification $\varphi$ with probability 1. The former requirement is reduced to the standard RL problem for MDP where the reward corresponds to the control cost. For the latter requirement, D. Sadigh et al. introduced rewards that evaluate the acceptance conditions in a DRA $R_{\varphi}$ for the LTL specification $\varphi$ [20]. Thus, we formulated the control problem as a reinforcement learning problem with multiple rewards.

We consider a learning problem of a set of actions, that is, a pattern satisfying the latter requirement for each state of the product MDP $M_{\varphi}$ by which we decide the satisfaction of the LTL formula. Thus, a control policy is described by a mapping from the state set of the product MDP to a pair of a pattern $\pi$ and an action $a$, where $a \in \pi$. The control objective is to learn the optimal pair $(\pi^*, a^*)$. The optimal pattern $\pi^*$ is a minimally restrictive set of actions such that an action by which the LTL control specification is satisfied with the probability less than 1 is removed from the set. The optimal action $a^*$ achieves the optimization of the discounted sum of the control costs in $\pi^*$ while the optimal action $a^*$ satisfies the
LTL specification in $\pi^*$. Thus, the optimal control is reduced to RL based optimal control consisting of sequentially decision making as shown in Fig. 1. At the first decision, we use rewards corresponding to the acceptance conditions of the DRA and learn a pattern that includes actions satisfying the LTL specification as many as possible so as to restrict the search of the optimal action in the pattern. At the second decision, we use the control costs and learn the optimal action in the pattern selected at the first decision. In the following, we formulate the RL based optimal control problem with the sequentially decision making.

First, we define a modified product MDP $\mathcal{P}$ from $\mathcal{M}_\varphi$ as follows.

**Definition 2:** Let $\mathcal{M}_\varphi$ be a product MDP. The modified product MDP is described by $\mathcal{P} = (S_\mathcal{P}, A_\mathcal{P}, P_\mathcal{P}, s_{P0}, Acc_\mathcal{P}, W_\mathcal{P}, g_\mathcal{P})$, where $S_\mathcal{P} = S_\varphi^\mathcal{P}$ is a set of states, $A_\mathcal{P} : S_\mathcal{P} \rightarrow 2^A \setminus \emptyset \times A$ is a function such that $A_\mathcal{P}(s_{\mathcal{P}}) = \{(\pi, a) \mid \pi \in 2^{A_\varphi(s_\mathcal{P})} \setminus \emptyset, a \in \pi\}$, $P_\mathcal{P} : S_\mathcal{P} \times A_\mathcal{P} \times S_\mathcal{P} \rightarrow [0,1]$ is a probability function defined as:

$$P_\mathcal{P}(s_{\mathcal{P}}, a_{\mathcal{P}}, s'_{\mathcal{P}}) = P_\varphi(s_{\mathcal{P}}, a, s'_{\mathcal{P}}) \quad (a_{\mathcal{P}} = (\pi, a),)$$

$s_{\mathcal{P}0} = s_{0_\varphi}$ is an initial state, $Acc_\mathcal{P} = \{Acc_i\}^{n_{Acc}}_{i=1} = \{(\varnothing_i, \emptyset_i)\}^{n_{Acc}}_{i=1}$ is a set of acceptance conditions defined as $\varnothing_i = G_\varphi^\mathcal{P}$ and $\emptyset_i = B_\varphi^\mathcal{P} = B_\varphi^\mathcal{P} \cup \text{Influx}(S_{\mathcal{P}})$,

$$\text{Influx}(S_{\mathcal{P}}) = \{(s_{\mathcal{P}}, s'_{\mathcal{P}}) \mid \exists a \text{ s.t.} \quad P_{\mathcal{P}}(s_{\mathcal{P}}, a, s_{\mathcal{P}}) > 0 \land s'_{\mathcal{P}} \in S_{\mathcal{P}}\},$$

$W_\mathcal{P} = \{W_{P_i}\}^{n_{Acc}}_{i=1}$ is a set of reward functions for $Acc_\mathcal{P}$, $W_\mathcal{P} : S_\mathcal{P} \times S_\mathcal{P} \rightarrow \mathbb{R}$ is defined as:

$$W_{P_\mathcal{P}}(s_{\mathcal{P}}, s'_{\mathcal{P}}) = \begin{cases} w_G > 0 & \text{if } (s_{\mathcal{P}}, s'_{\mathcal{P}}) \in \varnothing_i, \\ w_B > 0 & \text{if } (s_{\mathcal{P}}, s'_{\mathcal{P}}) \in \emptyset_i, \\ 0 & \text{otherwise}, \end{cases}$$

and $g_\mathcal{P}(s_{\mathcal{P}}, a_{\mathcal{P}}) = g_\varphi(s_{\mathcal{P}}, a)$ is a control cost function.

Note that the set of non-acceptance states $S_{\mathcal{P}}$ is merged into the set of non-acceptance transitions $B_\varphi^\mathcal{P}$ and the probability measure of the set of all sequences that satisfy $\varphi$ is unchanged because of (1). Then, if a sequence satisfies $\varphi$, the agent obtains a positive reward $w_G$ infinitely often and a negative reward $w_B$ finitely often. We define a policy $\mu : S_\mathcal{P} \rightarrow A_\mathcal{P}$ defined as $\mu(s_{\mathcal{P}}) = (\mu_1(s_{\mathcal{P}}), \mu_2(s_{\mathcal{P}})) = (\pi, a) \in A_\mathcal{P}(s_{\mathcal{P}})$.

Next, we introduce two kinds of optimal value functions $Q^{\mu}_\mathcal{P}(i = 1, 2, \ldots, n_{Acc})$ and $Q^{\mu}_2$ that are used for the first and the second decision, respectively.

The function $Q^{\mu}_1$ is an optimal value function about the LTL control specification for each acceptce condition $Acc_\mathcal{P}$, that is, $Q^{\mu}_1(s_{\mathcal{P}}, \pi)$ is the expected discounted sum of the rewards when transitions depend on an optimal policy $\mu^*$ and a pattern $\pi$ at the first decision making. Thus, the following optimal Bellman equation holds.

$$Q^{\mu\pi}_1(s_{\mathcal{P}}, \pi) = \sum_{t \in S_\mathcal{P}} \text{Pro}(s_{\mathcal{P}}, \pi, t) \cdot \left\{ R_{1t}(s_{\mathcal{P}}, \pi, t) + \gamma_1 \max_{\pi \in 2^{A_\varphi(s_{\mathcal{P}})} \setminus \emptyset} Q^{\mu\pi}_1(t, \bar{\pi}) \right\},$$

where $\text{Pro}(s_{\mathcal{P}}, \pi, t)$ is a probability of a transition from the state $s_{\mathcal{P}}$ to the state $t$ caused by the pattern $\pi$, $R_{1t}(s_{\mathcal{P}}, \pi, t)$ is a reward obtained by the transition from the state $s_{\mathcal{P}}$ to the state $t$ caused by the pattern $\pi$ for the acceptance condition $Acc_\mathcal{P}$, and $\gamma_1 \in (0, 1)$ is the discount rate for the evaluation of the LTL control specification. $\text{Pro}(s_{\mathcal{P}}, \pi, t)$ is reduced to the following equation.

$$\text{Pro}(s_{\mathcal{P}}, \pi, t) = \sum_{\sigma \in \pi} P_1(s_{\mathcal{P}}, \pi, \sigma) P_2(s_{\mathcal{P}}, \sigma, t),$$

where $P_1(s_{\mathcal{P}}, \pi, \sigma)$ is the decision probability of the action $\sigma$ at the state $s_{\mathcal{P}}$ and the pattern $\pi$, and $P_2(s_{\mathcal{P}}, \sigma, t)$ is the transition probability from the state $s_{\mathcal{P}}$ to the state $t$ by the occurrence of the action $\sigma$.

The function $Q^{\mu\pi}_2$ is an optimal value function about control costs, that is, $Q^{\mu\pi}_2(s_{\mathcal{P}}, \pi)$ is the expected discounted sum of the control costs when the pattern $\pi$ is selected at the first decision making under the optimal policy $\mu^*$. Thus, the following equation holds.

$$Q^{\mu\pi}_2(s_{\mathcal{P}}, \pi) = \min_{\sigma \in \pi} \sum_{t \in S_\mathcal{P}} P_2(s_{\mathcal{P}}, \sigma, t) \cdot \left\{ g([s_{\mathcal{P}}], \sigma) + \gamma_2 \min_{\pi \in 2^{A_\varphi(s_{\mathcal{P}})} \setminus \emptyset} Q^{\mu\pi}_1(t, \bar{\pi}) \right\},$$

where $g([s_{\mathcal{P}}], \sigma)$ is the control cost for the state $[s_{\mathcal{P}}]$, and $\gamma_2 \in [0, 1)$ is the discount rate for the cost evaluation. Note that the value function about control costs is defined independently for each acceptance condition. We make the following two assumptions [24], [25].

**Assumption 1:** $R_{1t}(s_{\mathcal{P}}, \pi, t)$ is given by

$$R_{1t}(s_{\mathcal{P}}, \pi, t) = R(s_{\mathcal{P}}, \pi) + W_{P_\mathcal{P}}(s_{\mathcal{P}}, t),$$

where $R(s_{\mathcal{P}}, \pi)$ is a pattern cost that evaluates the restriction of selectable actions by the pattern $\pi$ at the state $s_{\mathcal{P}}$ defined by

$$R(s_{\mathcal{P}}, \pi) = \begin{cases} R_G \frac{|A([s_{\mathcal{P}}])| - |\pi|}{|A([s_{\mathcal{P}}])| - 1} & \text{if } |A([s_{\mathcal{P}}])| \geq 2, \\ 0 & \text{if } |A([s_{\mathcal{P}}])| = 1, \end{cases}$$
and $R_c \in \mathbb{R}_{\leq 0}$ is a non-positive parameter that indicates the importance of less restrictiveness of the patterns.

If $R_c$ equals to 0 and $g_\rho(s_\rho, a_\rho) = 1$ for all $s_\rho$ and $a_\rho$, the optimal action is same as an optimal action defined in [20]. Therefore, the method in [20] is a special case of our proposed method. As $R_c$ decreases, the agent learns a policy that makes the discounted sum of control costs smaller and may select a pattern including an action by which the controlled MDP satisfies $\varphi$ with probability less than 1.

In general, an optimal action is not unique. So, for simplicity, we introduce a priority for the set of actions in such a way that the smaller the index of the action is, the higher its priority of the action is. We say that the action $\sigma_i$ has a higher priority than the action $\sigma_j$ if $i < j$.

**Assumption 2:** $P_1(s_\rho, \pi, \sigma)$ is given by

$$P_1(s_\rho, \pi, \sigma) = \begin{cases} 1 & \text{if } \sigma = \text{opt-action}^*(s_\rho, \pi), \\ 0 & \text{otherwise}, \end{cases}$$

where

$$\text{opt-action}^*(s_\rho, \pi) = \sigma_j,$$

and

$$j^* = \min_j \left\{ \min_{\sigma_j \in \pi} \sum_{i \in S_\rho} P_2(s_\rho, \sigma_j, t) \cdot \left\{ g([s_\rho], \sigma_j) + \gamma_2 \min_{\sigma_i \in \mathcal{S}^{\mathcal{A}(\mathcal{L}1)}} Q_2^\mu(t, \pi_i) \right\} \right\}.$$  

Assumption 2 means that the action $\sigma$ is selected with probability 1 at the state $s_\rho$ from the pattern $\pi$ in such a way that it is the highest priority among actions achieving the minimum expected discounted sum of the costs. This assumption is made for simplicity. Note that the probability $P_\rho$ in the optimal Bellman equation depends on the expected discounted sum of the control costs.

Using Assumptions 1 and 2, we rewrite $Q_1^\mu(s_\rho, \pi)$ as follows.

$$Q_1^\mu(s_\rho, \pi) = \sum_{i \in S_\rho} P_\rho(s_\rho, \pi, t) \cdot \{ R_1(s_\rho, \pi, t) + \gamma_1 \max_{\pi_1 \in \mathcal{S}^{\mathcal{A}(\mathcal{L}1)}} Q_1^\mu(t, \pi_1) \}$$

$$= \sum_{i \in S_\rho} \left( \sum_{\pi \in \mathcal{P}_\rho} P_1(s_\rho, \pi, \sigma) \cdot \{ R(s_\rho, \pi) + W_2^\mu(s_\rho, \pi) + \gamma_1 \max_{\pi_1 \in \mathcal{S}^{\mathcal{A}(\mathcal{L}1)}} Q_1^\mu(t, \pi_1) \} \right)$$

$$= R(s_\rho, \pi) + \sum_{\sigma \in \pi} P_1(s_\rho, \pi, \sigma) T_1^\mu(s_\rho, \sigma), \quad (2)$$

where

$$T_1^\mu(s_\rho, \sigma) = \sum_{\sigma \in \pi} P_1(s_\rho, \pi, \sigma) \sum_{i \in S_\rho} P_2(s_\rho, \sigma, t) \cdot \left\{ W_2^\mu(s_\rho, t) + \gamma_1 \max_{\pi_1 \in \mathcal{S}^{\mathcal{A}(\mathcal{L}1)}} Q_1^\mu(t, \pi_i) \right\}.$$  

We learn $P_1$ and $T_1^\mu$ in order to calculate $Q_1^\mu$ from (2). Note that $R$ is given before learning.

From the above discussion, the controller makes two decisions sequentially in the modified MDP $P$ with $Accept$ as shown in Fig.1. Such sequential decision making is different from that in normal MDPs. For the two kinds of value functions $Q_1^\mu$ and $Q_2^\mu$, we learn an optimal policy as follows. An optimal pattern at the state $s_\rho$ for the acceptance condition $Accept^\mu$ is given as follows.

$$\mu^*_1(s_\rho) = \pi_j,$$

where

$$j^* = \min_j \left\{ \max_{\pi_j \in \mathcal{S}^{\mathcal{A}(\mathcal{L}1)}} \max_{\pi_1 \in \mathcal{S}^{\mathcal{A}(\mathcal{L}1)}} Q_1^\mu(s_\rho, \pi_j) \right\}.$$  

An optimal action at the state $s_\rho$ for the acceptance condition $Accept^\mu$ under the optimal pattern $\mu^*_1(s_\rho)$ is given as follows.

$$\mu^*_2(s_\rho) = \text{opt-action}^*(s_\rho, \mu^*_1(s_\rho)).$$

Therefore, we obtain the following optimal control policy $\mu^*(s_\rho)$ at each state $s_\rho$.

$$\mu^*(s_\rho) = (\mu^*_1(s_\rho), \mu^*_2(s_\rho)).$$

Note that, even if the pattern $\mu^*_1(s_\rho)$ contains an action that leads to the non-acceptance transition or transitions to a livelock state, the action does not tend to be selected as the action $\mu^*_2(s_\rho)$ at the second decision making because the expected discounted sum of the control costs for such an action is not minimum in the pattern $\mu^*_1(s_\rho)$. We learn an optimal policy by optimizing these value functions.

Finally, we introduce a method for checking whether an MC $P_\mu$ generated by a policy $\mu$ and a product MDP $P$ satisfies $\varphi$ with probability 1. The set $S_\rho$ of states of $P_\rho$ is partitioned into a disjoint union of transient states $Tran^\rho$ and irreducible sets of recurrent classes $Rec^\rho$ as follows [26].

$$S_\rho = Tran^\rho \sqcup Rec^1_\mu \sqcup \cdots \sqcup Rec^n_\mu.$$  

We check whether $P_\mu$ satisfies $\varphi$ with probability 1 by computing strongly connected components of $P_\mu$ [1].

**Proposition 1:** Consider the MDP $M$ and the LTL formula $\varphi$. Let $P$ be the modified product of $M$ and $\mathcal{R}_\varphi$, and $\mu$ be a policy. $M_\mu$ satisfies $\varphi$ with probability 1 iff for all $j \in \{1, \ldots, n\}$, there exists $G_{i} \subseteq B_{i} \subseteq Acc \mu$ such that $G_{i} \cup Tran^\rho_{i,j} = \emptyset$ and $G_{i} \cup Tran^\rho_{i,j} \neq \emptyset$, where

$$Tran^\rho_{\mu,j} = \{(s_\rho, s_\rho') \mid \exists s_\rho' \text{ s.t. } (s_\rho \in Rec^\rho_{\mu,j}, s_\rho' \in Rec^\rho_{\mu,j}) \land P_\rho(s_\rho, \mu(s_\rho), s_\rho') > 0\}.$$

The proof of Proposition 1 is shown in Appendix A. We check whether the policy satisfies the LTL formula based on Proposition 1.

Shown in Algorithm 1 is a modified temporal difference learning algorithm. Shown in Algorithm 2 is an update algorithm used in Algorithm 1. It is assumed that the transition probabilities and the control cost function of $M$ are unknown a priori. Let $\alpha_1$ and $\alpha_2 \in [0, 1]$ be the rates of the update of
Algorithm 1: A proposed algorithm based on RL for $\mathcal{P}$

Input : $s_p'$ // A current state on $\mathcal{P}$  
Output: $a'$ // A selected action at $s_p'$

Persistent variables:
- Functions $Q_2, T_1, Q_{11}, R_{21}, R_{COST}, R_{opt}, R_{2o}$ are initialized as 0.
- A frequency counter table of a pair of a state $[s_p]$, and an action $a$ $\mathcal{N}_{sa}([s_p], a)$ is initialized as the empty table.
- A frequency counter table of a pair of ([s_p], a) and $[s_p']$, $\mathcal{N}_{sa}([s_p], a, [s_p'])$ is initialized as the empty table.
- An Estimated optimal policy $\mu_{opt} = (\mu_{1op}, \mu_{2op})$ is initialized.
- $s_p, \pi$ and $a$ are initialized as NULL.

1 if ResetConditionMet() returns TRUE then
2     $s_p'=$ResetRabinState($s_p'$);
3 else if $s_p \neq$ NULL then
4     UpdateFunctions($s_p, a, s_p'$);
5     $\mu_{1op}(s_p) =$ opt_pattern($s_p$);
6     $\mu_{2op}(s_p) =$ s.t. $Pr_01(s_p, \pi_{opt}(s_p), \sigma) = 1$;
7     if $s_p'$ has already visited before then
8         $\pi'$ is updated from $\mu_{1op}(s_p')$ using the $\epsilon$-greedy method and $a'$ is updated s.t. $Pr_01(s_p', \pi', a') = 1$;
9     else
10        $\pi'$ is updated at random and $a'$ is determined from $\pi'$ at random;
11     $s_p = s_p', \pi = \pi', a = a'$;

Q_1$ and $Q_2$, respectively. The function ResetConditionMet() at line 1 in Algorithm 1 returns TRUE if the behavior is livelock in a sufficiently long specified time interval. The function ResetRabinState($s_p'$) at line 2 in Algorithm 1 initializes the current state of $\mathcal{R}_p$. Using these functions, the agent avoids visiting states that need not explore. These functions are valid when $\varphi$ is constructed from $FG\rho'$, $GF\rho'$, $F\rho'$, or $G\rho$ because the updates of estimation functions are independent of the initial state for these formulas. The function opt_action used at line 12 in Algorithm 2 is defined as follows.

$$\text{opt\_action}(s_p, \pi) = \sigma_j,$$

where

$$j^* = \arg \min_{j \in \{1, \ldots, n_{Act}\}} \min_{\sigma \in \pi} \sum_{t \in \mathcal{P}} R_{opt}(s_p, \sigma_j, t) \cdot \left( R_{COST}([s_p], \sigma_j) + \gamma_2 \min_{\pi \in \mathcal{A}(t, \pi)} Q_2(t, \pi) \right).$$

The function opt_pattern used at line 5 in Algorithm 1 is defined as follows.

$$\text{opt\_pattern}(s_p) = \pi_j,$$

where

$$j^* = \arg \max_{j \in \{1, \ldots, n_{Act}\}} \max_{\pi \in \mathcal{A}(t, \pi) \setminus \emptyset} \max_{i} Q_{1i}(s_p, \pi_j).$$

V. ILLUSTRATIVE EXAMPLE

In this section, as an example, we consider a 5 $\times$ 5 grid world, which is given in [20], where an agent is required to visit cells labeled $A$ and $B$ infinitely often, while avoiding
Fig. 2: A grid world example with arrows implies control costs 1000. An initial state’s location is (0,3) denoted by a solid square.

Fig. 3: A DRA constructed from $\phi$. There is only one valid acceptance condition. Blue, red and black arrows represent non-acceptance, acceptance, and neutral transitions, respectively. This requirement is described by the following LTL formula $\phi$.

$$\phi = \text{GF}A \land \text{GFB} \land \text{G} \neg C.$$

minimum values are 0.0001. We linearly decreased the rates while learning the policy.

Shown in Fig. 4 are the results of the learning algorithm. The arrows represent direction for which the agent moved for 5000 steps by the obtained optimal policy from the initial state. We confirmed that both policies satisfy the LTL formula $\phi$ with probability 1. Shown in Fig. 5 is a ratio $\eta$ defined by the following equation for each episode $ep$.

$$\eta(ep) = \frac{X_1(ep)}{X_{21}(ep) - X_{22}(ep)},$$

where $X_1(ep)$ is the number of times that matched between an obtained optimal action and an optimal action calculated by dynamic programming(DP) at the non-livelock state in this example, $X_{21}(ep)$ is the total number of steps in the episode $ep$, that is, $X_{21}(ep)$ equals to 1000, $X_{22}(ep)$ is the number of times that the agent is in the livelock state. Shown in Fig. 6 is a sample path for the obtained policy of the case (b). As you can see on cell (1,1), the optimal
VI. CONCLUSION

We considered an uncertain MDP with control cost and an LTL control specification. We have proposed a method for designing a policy based on RL such that the controlled modified product MDP satisfies the control specification with probability 1 and the policy minimizes the expected discounted sum of the costs. In the method, we transformed the problem into the optimization of the value functions and we applied temporal difference learning algorithm. It is future work to prove a condition for which the proposed algorithm obtains an optimal policy. It is also future work to prove the convergence of the value function algorithm.
